ABSTRACT

Question This systematic review explores two questions: what parenting difficulties are experienced by mothers with borderline personality disorder (BPD); and what impact do these have on her children?

Study selection and analysis Studies had to include mothers with a diagnosis of BPD, who was the primary caregiver to a child/children under 19 years. PsycINFO and MEDLINE were screened (update: July 2014), yielding 17 relevant studies.

Findings Mothers with BPD are often parenting in the context of significant additional risk factors, such as depression, substance use and low support. Interactions between mothers with BPD and their infants are at risk of low sensitivity and high intrusiveness, and mothers have difficulty in correctly identifying their emotional state. Levels of parenting stress are high, and self-reported competence and satisfaction are low. The family environment is often hostile and low in cohesion, and mothers with BPD show low levels of mind-mindedness but high levels of overprotection of older children. Outcomes for children are poor compared with both children of healthy mothers, and mothers with other disorders. Infants of mothers with BPD have poorer interactions with their mother (e.g., less positive affect and vocalising, more dazed looks and looks away). Older children exhibit a range of cognitive-behavioural risk factors (e.g., harm avoidance, dysfunctional attitudes and attributions), and have poorer relationships with their mothers. Unsurprisingly, given these findings, children of mothers with BPD have poorer mental health in a range of domains.

Conclusions This review highlights the elevated need for support in these mother–child dyads.

BACKGROUND

Borderline personality disorder (BPD) affects around 0.7–1% of the British population.1 Although there is much controversy over its definition and diagnosis, it is generally agreed to be characterised by difficulties in emotion regulation, and interpersonal relationships. Some individuals with BPD struggle with empathy, resulting in difficulties identifying and understanding others’ feelings. Relationships are often unstable and of high intensity, characterised by insecurity, hostility and lack of trust. They often exhibit chronic concerns about rejection and abandonment, most pronounced in close interpersonal relationships. Anxiety and depression are common in BPD, as are impulsivity and risk-taking.2

Individuals with BPD can also experience disturbances in their sense of identity, exhibiting unstable self-image, excessive self-criticism, and feelings of emptiness.3 Their self-presentation can fluctuate depending on the group or situation they are in, with the sufferer’s sense of identity being experienced as dependent on a specific relationship.3

It is now widely accepted that mental health difficulties in parents impact on parenting and, subsequently, on outcomes for the child.4–7 However, despite the clear need for it, there is a paucity of research into the influences of parental BPD on parent as well as child. To the best of our knowledge, no attempt has been made at synthesis of the findings of this research, in order to provide a better understanding of the consequences of maternal BPD.

OBJECTIVES

Considering that BPD is most commonly diagnosed in women,8 many of whom will be mothers,9 the current review will draw together research considering maternal BPD. The aim is to systematically synthesise the findings of this research, in order to provide a better understanding of the consequences of maternal BPD.

Two questions are explored:
1. Are there deficits and difficulties in the parenting of mothers with BPD?
2. What difficulties are experienced by children of mothers with BPD?

STUDY SELECTION AND ANALYSIS

Searches were conducted on PsycINFO and MEDLINE.

The search string was: “child*” AND (“borderline personality disorder” OR “emotionally unstable personality disorder”). Figure 1 depicts the search process at the final date for checking: 10 July 2014. Non-English language articles were removed, leaving 3405 articles. After removing duplicates, there remained 2579. In stage 1, titles and abstracts were read against inclusion/exclusion criteria by LP, and a random 10% were re-rated by an independent researcher. Agreement was 97.8%. Disagreements were resolved on discussion.

This resulted in removal of 2510 articles, leaving 70. At stage 2, each full paper was scrutinised against the inclusion/exclusion criteria (table 1). Consequently, 54 papers were excluded (the reasons are summarised in table 2).

This left 17 papers that satisfied the inclusion/exclusion criteria. Reference lists were scrutinised for titles relevant to the review. This revealed no further papers. Eight prominent authors were contacted, and asked to identify any additional studies, but none were found.

Quality appraisal

The Strengthening the Reporting of Observational studies in Epidemiology (STROBE) checklist10 is widely accepted as a tool for improving the quality of reporting of observational studies.11 The cross-sectional variant lists 22 areas that are required for highest quality reporting of cross-sectional research. For this review, each area was rated on a five-point scale, and scores averaged to provide a total score. Four papers were categorised as ‘average to above average’, and 13 as ‘above average to good’ (terms based on the Jadad scale,12 which ranges from 0 (bad) to 5 (good); table 3). Five randomly selected articles were re-scored by an independent rater. Inter-rater reliability was assessed using Spearman’s correlation, giving a strong, positive correlation between quality ratings, $r_s=0.95, n=5$, $p=0.014$. The primary researcher’s ratings were, therefore, accepted.

FINDINGS

Maternal BPD and parenting

Fourteen studies assessed parenting (table 4). Across the age range, these studies showed that mothers with BPD were parenting in the
context of many factors that are known to put parenting and children’s mental health at risk. All studies that explored parental depression showed this to be significantly elevated in mothers with BPD, compared with a range of control groups.13–16 Feldman et al17 noted higher drug and alcohol abuse in parents with BPD (present in 88%), and White et al18 noted that their sample of parents with BPD used more alcohol during pregnancy. Some studies15 19 noted that mothers with BPD were more likely than control groups to be parenting without the support of a partner, or within a household that frequently changed in its composition.17 This study also noted that children of BPD parents had experienced more changes in school, and more non-maternal care than controls.

The impacts of BPD on parenting are now presented by age of child: babies and young children; older children.

Babies and young children
Parenting in the context of BPD is not well understood, but perhaps the greatest attention has been devoted to the newborn and toddler age group. All studies of this age group conclude that mothers with BPD parent differently, on average, to a range of control samples.

Interaction style
White et al16 studied mothers with BPD, major depressive disorder (MDD) and healthy controls, in interaction with their 3-month-old infants. Mothers with BPD smiled less, touched and imitated their infants less and played fewer games with their babies. Lack of sensitivity in interactions with offspring is a recurring theme. Crandell et al20 observed mothers of 2-month-old infants in face-to-face interaction with their child. Compared with healthy controls, mothers with BPD were less sensitive in their interactions, and more intrusive. Observers subsequently rated their interactions as less ‘satisfying’ and ‘engaged’. Similarly, Newman et al13 rated mothers with BPD of 16-month-olds as less sensitive than healthy controls, and Hobson et al21 also found their mothers with BPD to be more ‘intrusively insensitive’ in their interactions with their 1-year-olds, compared with healthy controls, and these differences remained once demographic differences between the groups were controlled. Kiel et al22 found that, in comparison with healthy control mothers, mothers with BPD showed less positive affect in response to infant distress, and took longer to do so. As infant distress increased in duration, mothers with BPD were increasingly likely to show insensitive behaviour towards their child. These differences remained even when group differences in anxiety and depression were controlled. Hobson et al23 also explored affective communication, this time in mothers with BPD of toddlers. This was found to be disrupted, in comparison to a healthy control group and a depressed control group. Mothers with BPD were also more likely to exhibit a ‘fear/dis-orientation’ response to their child’s attachment bids, a pattern that has been linked to disorganised attachment in the child.24 Finally, musicologists recorded interactions between mothers and their 1-year-olds,25 They found that, in comparison with healthy controls, interactions where the mother had BPD differed in ‘temporal qualities and musical organisation’. Mothers with BPD paused longer and used more non-vocal sounds than controls.

Emotion recognition
Ability to identify infants’ emotions was disrupted in BPD mothers of children aged 3–14 months.26 Compared with healthy controls, mothers with BPD were less accurate at identifying emotions in photographs of their own and unfamiliar children. In particular, they were prone to labelling neutral expressions as ‘sad’. This sample of mothers was also likely to self-report overprotection of their child.

Activity structuring
On a pragmatic level, mothers with BPD were found to be less good at structuring their children’s activities, in comparison with healthy controls.27
Table 1 Inclusion and exclusion criteria

BPD, borderline personality disorder; DSM, Diagnostic and Statistical Manual of Mental Disorders.

Parenting stress/self-competence

Unsurprisingly, given the results described above, mothers with BPD, of children in this age group have been shown to self-report higher parenting stress, lower competence, and lower satisfaction in the parenting role than control parents.

Older children

Family environment

Using the Family Environment Scale, Feldman et al (17) showed that mothers with BPD rated their family as lower in cohesion and organisation, and higher on conflict than the control group, which comprised mothers with other types of personality disorder. Children in this study (mean age 11 years) were also more likely to rate their family as low in cohesion and expressiveness if their parent was diagnosed with BPD as opposed to another personality disorder. Similarly, Herr et al (18) found that BPD symptoms in mothers were correlated with ratings of maternal hostility given by their 15-year-old offspring. Feldman et al (17) concurred, finding that verbal abuse, physical abuse and witnessing of violence were common in their sample of children of mothers with BPD, even in comparison with children whose parents had other personality disorders.

Mind-mindedness

Schacht et al (16) explored mind-mindedness (parental ability and willingness to think about their child’s mental state in parents of children aged 39–61 months). They found evidence of reduced mind-mindedness in interviews with mothers with BPD, in comparison with healthy controls, a difference that remained once maternal depression was controlled.

Overprotection

Two studies found that mothers with BPD scored higher on a measure of overprotection of children. Children (mean age 11 years) of mothers with BPD rated their mothers as less encouraging of independence than children whose mothers had other personality disorders. Similarly, mothers with BPD were reported to be more overprotective by their children aged 11–18 years, in comparison with healthy controls and controls with depressive illness and other personality disorders. It should be noted, however, that children of mothers with BPD might be living in environments that are more risky than average children, and that this higher reported overprotection might be advantageous in these conditions.

Parenting stress/satisfaction

Finally, given the differences in parenting reported above, it is not surprising that Herr et al (18) noted chronic stress in the relationship between mothers with high levels of BPD symptomatology and their 15-year-old offspring, and Feldman et al (17) found extremely low self-reported satisfaction with their family (at the 1st centile) in mothers with BPD.

Influence of maternal BPD on children’s outcomes

Twelve papers measured the association between maternal BPD and child outcomes (see table 4). As above, the outcomes are reported separately for babies/toddlers and for older children.

Babies/toddlers

Across five studies, babies/toddlers of mothers with BPD behaved differently to those of control mothers. Crandell et al. found that when exposed to a 90 s ‘still-face’ challenge, 2-month-old infants of mothers with BPD were more likely to look away, or to look dazed than children of healthy controls. In a standard face-to-face interaction with their mother, children of mothers with BPD showed less positive affect, and again, more dazed looks. In similar studies of face-to-face interactions between mothers and their infant children, children of mothers with BPD were shown to smile less, vocalise less, avert their gaze more, appear more fearful and be less soothable, be less responsive to mothers’ bids for interaction, and show less optimally ‘involving’ behaviours towards their mothers than control mothers. They also displayed lower ‘availability for positive engagement’ with and fewer positive looks towards a stranger, and had lower ‘behavioural organisation’ and mood state.

Older children

Cognitive and behavioural risk factors

Older children of parents with BPD showed a range of cognitive and behavioural risk factors in comparison with control children. Herr et al. found that maternal BPD symptoms were negatively correlated with Harter social acceptance scores, and ability to make close friends in their 15-year-old sample, and that this relationship held even after maternal depression was controlled. Schacht et al. found that preschool-aged children of women with BPD had poorer theory of mind when given a false-belief task, and were poorer at both labelling pictures of emotional faces and identifying possible causes of the depicted emotions. Macfie and Swan found that their children aged 4–7 years of mothers with BPD displayed more negative self-representations, more fantasy-proneness and fantasy-reality confusion, lower narrative coherence and more intrusion of traumatic material when participating in a series of role-play scenarios, when compared with children of healthy mothers. Abela et al. found their children aged 6–14 years of mothers with BPD to have a more negative attribution style, more dysfunctional attitudes, a more ruminative response style, engage in more reassurance-seeking, and have higher levels of self-criticism than a sample of children of depressed mothers. Finally, in the study by Barnow et al., children (aged 11–18 years) showed excessive harm-avoidance, in comparison with children of depressed mothers and healthy mothers.

Parent–child relationships

As well as these elevated cognitive and behavioural risk factors, children seem to have a higher risk of problematic relationships with their parents with BPD. Four studies showed that children of mothers with BPD had elevated instances of disrupted attachment styles. Additionally, in role-play tasks, children of mothers with BPD (aged 4–7 years) showed excessive role-reversal and fear of abandonment in their 15-year-old sample, and that this relationship held even after maternal depression was controlled. Schacht et al. found that preschool-aged children of women with BPD had poorer theory of mind when given a false-belief task, and were poorer at both labelling pictures of emotional faces and identifying possible causes of the depicted emotions. Macfie and Swan found that their children aged 4–7 years of mothers with BPD displayed more negative self-representations, more fantasy-proneness and fantasy-reality confusion, lower narrative coherence and more intrusion of traumatic material when participating in a series of role-play scenarios, when compared with children of healthy mothers. Abela et al. found their children aged 6–14 years of mothers with BPD to have a more negative attribution style, more dysfunctional attitudes, a more ruminative response style, engage in more reassurance-seeking, and have higher levels of self-criticism than a sample of children of depressed mothers. Finally, in the study by Barnow et al., children (aged 11–18 years) showed excessive harm-avoidance, in comparison with children of depressed mothers and healthy mothers.

Mental health outcomes

In almost all instances where mental health outcomes were explored, children of parents with BPD fared worse than control children, even when these control children had parents with significant mental health difficulties, for example, Weiss et al. found that children of mothers with BPD (mean age around 11 years) had lower Child Global Assessment Schedule (CGAS) scores than children of mothers with other personality disorders, and that the mean of these scores was in the ‘non-functional’ range. The one exception was the study by Abela et al. which did not find increased difficulties with self-esteem or dependence in children aged 6–14 years of mothers with BPD, compared with children of depressed mothers. It should be noted that lack of power (there were only 20 mothers with BPD) in this study could have accounted for this null finding.

Three studies that explored symptoms of emotional disorders found that these were higher in children of parents with BPD compared with control groups: Barnow et al. compared children aged 11–18 years of mothers with BPD, children of mothers with depression, and mothers with other personality disorders, and found the children of mothers with BPD to have signs of higher levels of emotional disorder and of suicidal ideation. Indeed, 9% of children whose mothers had BPD had already attempted suicide, compared with 2% of children of healthy mothers. Abela et al. studied children aged 6–14 years and found that those with a mother with BPD had experienced more depression (45% had suffered a major depressive episode), than a sample of children whose mothers were currently depressed. This study explored a number of potential cognitive and behavioural risk factors in children (see above) and found that these partly mediated the relationship between maternal BPD and children’s depression. Finally, Herr et al. found that symptoms of BPD in mothers were positively associated with depression in their 15-year-old youth, although in this instance, this relationship disappeared when maternal depression was controlled.

Two studies explored the relationship between maternal BPD and children’s externalising symptoms. In both cases, there was a positive association. Weiss et al. reported that children (with a mean age of 11) whose mother had BPD, were more likely to have a behavioural disorder or attention deficit disorder than the children in the control group, whose parents had a range of other personality disorders (but not BPD). Barnow et al. also found more parent-reported symptoms of (11–18 years old) children’s behavioural problems in their sample of mothers with BPD, in comparison with children of healthy controls.

CONCLUSIONS AND CLINICAL IMPLICATIONS

In studies employing a range of designs and comparison groups, and all of reasonable quality, mothers’ BPD diagnosis was clearly associated with differences in parenting. In the studies of early childhood, most of which focussed on mother–child interactions, maternal BPD was associated with reduced sensitivity and increased intrusivity towards the child. This is, perhaps, not surprising, given the finding that mothers with BPD found it difficult to correctly identify emotions in photographs of both their own and strangers’ children. Mothers with BPD also found it more difficult to structure their young child’s activities and in later childhood were rated as having poorer levels of family organisation. The family environment where mothers had BPD was characterised by high levels of hostility, and low levels of cohesion, according to both parent and child reports. Mothers with BPD were reported to show high levels of overprotection towards their children but to have lower levels of mind-mindedness, that is, a reduced ability to reflect on their child’s internal world.

Given these difficulties in parenting experienced by mothers with BPD, it is perhaps unsurprising that they reported feeling less competence and satisfaction in the parenting role. In a number of studies, they also found parenting to be a very stressful task. The children of mothers with BPD experience a range of negative outcomes. In infancy, they appear to experience interactions with their mother as less satisfying, showing signs of less positive affect, more looking away, more dazed looks and fewer
vocalisations. Subsequently, these children experience a range of cognitive–behavioural risk factors. Compared with control children, they had more difficulties with friendships, poorer theory of mind, difficulties labelling and understanding the causes of common emotions, increased fantasy proneness and difficulty distinguishing fantasy and reality, increased negative attributional style, dysfunctional attitudes, rumination and self-criticism. They also experience difficulties in the mother–child relationship, with four studies reporting high levels of disrupted attachment styles, and in role-play scenarios elevated levels of role-reversal with parents, fear of abandonment, and negative expectations of parents. These factors are known to put children at risk of poor mental health outcomes, and indeed, this appears to be the case. Children of mothers with BPD had poorer mental health than control groups, showing substantially elevated levels of depression, suicidality, fearfulness, and behaviour problems and attention deficit disorder.

Most notably, many studies included parents with other diagnoses as control groups, typically other severe presentations, such as MDD and other personality disorders. In most instances, mothers with BPD (and their children) had greater difficulties and poorer outcomes than any of these groups, underscoring the particularly severe difficulties that are faced by these mothers and their children. But, can a causal relationship between BPD and impaired parenting, and subsequently between parenting and child outcome be assumed? Given the difficult circumstances in which mothers with BPD are often parenting, increased likelihood of lone-parenting, depression, substance misuse, we must consider the possibility that it is these factors, rather than BPD that cause the poor outcomes for their children. However, many of the studies reported here controlled for maternal depression and/or demographic factors, and in almost every instance, the relationship between BPD and impaired parenting, or BPD and child outcomes, was upheld. Unfortunately, few studies have examined both parenting risks and child outcomes, and explored the mediating role of the former. However, in the handful of studies that did this, it was apparent that the relationship between parent and child mental health was mediated by parenting difficulties.

The current systematic review is subject to some limitations. First, owing to a lack of resource for translation, it excluded all papers that were not in English. Second, although all studies were deemed to be of a reasonable standard, all were subject to some risk of bias. In particular, all were cross-sectional in design, which limits the conclusions that may be drawn. Similarly, although all studies made some attempt to confirm a diagnosis of BPD in participants, in some cases, this was achieved only by means of self-report questionnaire measures, which is not an optimally valid approach. Similarly, parents were often the primary reporter on children’s outcomes, which is likely to have introduced a bias. Almost all the studies were very small (see table 4), meaning that they were probably underpowered to detect smaller group differences (although it should be noted that most studies found significance between groups on almost all their outcome measures). However, the very small samples of mothers with BPD that were reported here employed samples that are highly representative of the diverse population of mothers with BPD. Most employed clinical samples, which is likely to be over-representative of the severe end of the disorder. It should be noted that all these studies represent the ‘average’ parent with BPD, and it is likely that many such parents actually manage very well and have children with good outcomes. The findings of this review show how very difficult parenting is for mothers with a diagnosis of BPD. These difficulties are probably more severe than for families where a parent has MDD or another personality disorder. Furthermore, it seems likely that if these mothers are not supported in the parenting role, their children are at risk for a range of poor outcomes. While interventions exist for women with BPD, there are currently no interventions that aim to reduce the risk to their children. These families do not deserve to be as overlooked as they have been, as there is evidence, even though it is limited, that they are in particular need of help.
